Chapter 11

Topological Semimetals

In a lattice model for a $d$ dimensional topological insulator, transitions between topological and trivial regimes can be induced by tuning some parameter $\lambda$. We can promote this parameter to a momentum, and thus obtain a $d+1$ dimensional lattice model. This will be a topological semimetal, also called 0-gap insulator, where the bands touch at separated points. The band touching points are called Weyl nodes, they carry a topological charge, and therefore are topologically protected: continuous changes of parameters can move them, but cannot open a gap. To transition to an insulator, all Weyl nodes have to fuse with other nodes with opposite charge. Topological semimetals also have surface states, whose density depends on the orientation of the surface with respect to the crystallographic axis.

11.1 Coupling SSH Chains for a Two-dimensional Weak Topological Insulator

We construct a two-dimensional chiral symmetric lattice model by connecting several SSH chains to each other through nearest-neighbor hopping. The interchain hopping amplitudes $w_y$ connect sites on opposite sublattices, so chiral symmetry is respected. As shown in Fig. 11.1, we obtain a so-called brick-wall lattice, rotated by 45 degrees.

The corresponding bulk momentum-space Hamiltonian reads,

$$H_{\text{C2D}}(k) = \begin{pmatrix} 0 & v + w_x e^{-ik_x} + w_y e^{-ik_y} \\ v + w_x e^{ik_x} + w_y e^{ik_y} & 0 \end{pmatrix}.$$  \hspace{1cm} (11.1)

Here we used $v$ for the intracell hopping amplitudes, and $w_x$ for the hopping along the chains. Expressed in terms of the Pauli matrices, this reads,

$$\hat{H}_{\text{C2D}}(k) = (v + w_x \cos k_x + w_y \cos k_y) \hat{\sigma}_x + (w_x \sin k_x + w_y \sin k_y) \hat{\sigma}_y.$$  \hspace{1cm} (11.2)

The system has chiral symmetry, inherited from the SSH chains, because of the
Figure 11.1: Geometry of the model. Filled (empty) circles are sites on sublattice A (B), each hosting a single state. They are grouped into unit cells, one of which is indicated by a dotted line. The intracell hopping amplitudes \( v \) are shown in thick lines, the intercell hopping amplitudes along the \( x \) and \( y \) axes, \( w_x \) and \( w_y \), are shown in thin and dashed lines. The left and right edge regions are indicated by blue and red shaded background.

way we introduced with the interchain hoppings.

\[
\hat{\sigma}_z \hat{H}_{\text{C2D}}(k) \hat{\sigma}_z = -\hat{H}_{\text{C2D}}(k). \tag{11.3}
\]

It also has inversion symmetry and time-reversal symmetry,

\[
\begin{align*}
\text{Inversion symmetry} & : \quad \hat{\sigma}_x \hat{H}_{\text{C2D}}(k) \hat{\sigma}_x = \hat{H}_{\text{C2D}}(-k); \tag{11.4} \\
\text{Time-reversal symmetry} & : \quad \hat{H}_{\text{C2D}}(k) = \hat{H}_{\text{C2D}}^*(k). \tag{11.5}
\end{align*}
\]

For the properties we focus on now, the symmetries besides chiral symmetry are not important. They can be broken, e.g., by making the intracell hopping complex, which modifies Eq. (11.2) by an extra term \( \text{Im}(v) \hat{\sigma}_y \).

11.1.1 Weak Topological Insulator

We expect interesting physics if the two-dimensional model is composed of topological SSH chains \( (w_y > v) \) that are weakly coupled, \( w_y \ll w_x, v \). We then have what is called a weak topological insulator: a two-dimensional insulator with a weak topological invariant, the \( k_y \)-independent winding number along the \( k_x \) axis.

A weak topological insulator has protected edge states, as can be understood by treating the interchain hopping \( w_y \) as a perturbation. These edge states can be seen on a numerical example shown in Fig. 11.2. Consider a straight boundary at some angle \( \alpha \) with the \( x \) axis. For \( w_y = 0 \), we have a zero-energy eigenstate for each chain that
11.2 Transition from Trivial to Weak Topological Insulator is Broadened: Topological Semimetal

Consider how the two-dimensional chiral symmetric model can be tuned using the intercell hopping along the chains, $w_x$, from topologically trivial to a weak topological insulator. In the case of no interchain hopping, $w_y = 0$, we have a trivial insulator with $w_x < v$, and a weak topological one with $w_x > v$. There is a sudden transition from trivial to weak topological insulator at $w_x = v$, when the gap closes at $k_x = \pi$, which corresponds to a line spanning the two-dimensional Brillouin zone. We will see that in the presence of an interchain hopping $w_y$, this transition is broadened. The gap closes only at isolated momenta, the so-called nodes, which traverse the Brillouin zone as the control parameter drives the system through the transition.

To build on our understanding of the topology in the SSH model, we can demote $k_y$ to a parameter, much in the same way as we did when we connected the Qi-Wu-Zhang model to the Thouless charge pump. Looking at the bulk Hamiltonian in this way, we have a continuous set of SSH models, with complex intracell hopping parameter $v_{SSH}(k_y) = v + w_y \cos k_y + iw_y \sin k_y$, and intercell hopping $w_{SSH}(k_y) = w_x$. The corre-
CHAPTER 11. TOPOLOGICAL SEMIMETALS

Figure 11.3: The curve on the $d_x - d_y$ plane, traced by the bulk Hamiltonian $\hat{H}_{C2D}(k_x, k_y)$, at a fixed $k_y$, as $k_x$ is tuned across the Brillouin zone, can be trivial (left, winding number 0), or topological (right, winding number 1). If, as in the example shown, none of $|v|$, $|w_x|$, and $|w_y|$ is bigger than sum of the other two, for some value of $k_y$, we will have the trivial, for others, the topological case. We then must have an intermediate value of $k_y$ where the gap closes: a node.

Corresponding curves in the $d_x - d_y$ plane, as illustrated in Fig. 11.3, are circles of radius $w_x$, whose center is at $(v + w_x \cos k_y, w_y \sin k_y)$. Thus, as we tune $k_y$, the center of the circle is taken on a circle of radius $w_y$ around $(v, 0)$. If, as in the example shown, none of $|v|$, $|w_x|$, and $|w_y|$ is bigger than sum of the other two, for some value of $k_y$, we will have the trivial, for others, the topological case. We then must have two values of $(k_y, k_x)$ where the gap closes: the nodes. We have

\[
\begin{align*}
\text{If } & w_x < v - w_y : & \text{Trivial} \\
\text{If } & v - w_y < w_x < v + w_y : & \text{Topological semimetal} \\
\text{If } & v + w_y < w_x : & \text{Weak topological}.
\end{align*}
\]

We show the dispersion relations, and with edge states for x edge, y edge, in Fig. 11.4. See Exercise 11.8.

In the topological semimetal case we have isolated points in the Brillouin zone where the gap closes. This is all quite natural when describing the model as a set of 1-dimensional chiral symmetric topological insulators, but in the full 2D model, it can appear strange.

11.2.1 Gap closing points

In the topological semimetal phase we do not have a bulk gap: it closes at single points in the Brillouin zone, the so-called nodal momenta $k$. The nodes are the solutions of the equations,

\[d_x(K_x, K_y) = 0; \quad d_y(K_x, K_y) = 0.\]  \hfill (11.6)

These are two equations for two variables $k_x$ and $k_y$, so we expect only isolated, point-like solutions, if any.

Continuously varying the parameters $w_x$, $w_y$, and $v$, each isolated pointlike node will be driven along a path in the Brillouin zone. For our two-dimensional model
11.2. TOPOLOGICAL TRANSITION BRODENED

Figure 11.4: Transition from trivial insulator to a weak topological insulator, obtained by tuning $w_x$. Interchain coupling is $w_y = 1/3$, and parameters are set so that $w_x + w_y + \nu = 2$. From left to right, $\nu, w_x = (1.1, 0.566), (0.95, 0.716), (5/6, 5/6), (0.716, 0.95), (0.566, 1.1)$. Top row: cut along $y$. Bottom row: cut along $x$. Large (red) dots indicate edge states (whose wavefunction has over 40% weight within the first 6 unit cells of the total of 30 unit cells)
Figure 11.5: Paths of the nodes in the Brillouin zone. Left: $v = 1, w_y = 1/3$, tune $w_x$. Right: $v = 1, w_y = 5/3$, tune $w_x$.

system, the gap closing requirements read

$$-v = w_x \cos K_x + w_y \cos K_y; \quad w_x \sin K_x = -w_y \sin K_y,$$

and can be solved as

$$w_x = \sqrt{(v + w_y \cos K_y)^2 + w_y^2 \sin^2 K_y},$$
$$K_x = \arctan2(-w_y \sin K_y, -v - w_y \cos K_y),$$

using the $\arctan2$ function, which returns $\phi \in (-\pi, \pi]$, if supplied with arguments $a \sin \phi$, $a \cos \phi$ for any $a > 0$.

Using a parameter, e.g., $w_x$, to tune the system across a broadened topological phase transition, we find that nodes are first born pairwise, then driven in opposite directions in the Brillouin zone, then annihilate pairwise. Examples with $v = 1, w_y = 1/3$, and $v = 1, w_y = 5/3$, are shown in Fig. 11.5. In our two-dimensional model this follows from inversion symmetry: nodes must come in inversion symmetric pairs of $(K_x, K_y) \leftrightarrow (-K_x, -K_y)$, and

If $v > w_y$ : $v - w_y \leq w_x \leq v + w_y; \quad M \rightarrow X_x; \quad (11.10)$
If $v < w_y$ : $w_y - v \leq w_x \leq v + w_y; \quad X_y \rightarrow X_x. \quad (11.11)$

However, even if inversion symmetry is broken, nodes can only be born and annihilated pairwise. As we show next, this has a deeper, topological reason.

### 11.3 Topological Charge of Nodes

The nodes in the topological semimetal, i.e., the isolated pointlike gap closing points, carry a topological charge, and are hence topologically protected. We show this first
for the two-band model, and then generalize.

### 11.3.1 Two-band Model: Charge is Winding of \( \vec{d} \) Around Node

Since our two-dimensional semimetal is a two-band model, we can gain more insight into the nature of the nodes by taking a look at the \( \vec{d} \) field, defined by \( \tilde{H}(k_x, k_y) = \vec{d}(k)\tilde{\sigma} \). An example for \( w_x = w_y = v = 1 \) is shown in Fig. 11.6. Here, the two nodes are at \( K_x = -K_y = \pm \frac{2\pi}{3} \), and you can see that the \( \vec{d} \) field winds around these points. We can put the calculation into a convenient form using

\[
d(k) = d(k) \cos(\phi(k))\tilde{x} + d(k) \sin(\phi(k))\tilde{y},
\]

(11.12)

where \( \tilde{x} \) and \( \tilde{y} \) are unit vectors along the two axes.

Put a discrete lattice on the Brillouin zone. We assign numbers to the vertices, edges, and plaquettes of the lattice, as

vertex \( k_a : \phi(k_a) = \text{atan2}(d_x(k_a), d_y(k_a)); \) (11.13a)

edge \( k_a \rightarrow k_b : \phi_{ab} = \text{arg}(e^{i\phi(k_b) - i\phi(k_a)}); \) (11.13b)

plaquette \( p : Q_p = \frac{1}{2\pi} (\phi_{ab} + \phi_{bc} + \phi_{cd} + \phi_{da}); \) (11.13c)

where the plaquette \( p \) has boundary \( a \rightarrow b \rightarrow c \rightarrow d \rightarrow a \). The quantity \( Q_p \in \mathbb{Z} \) counts the vorticity of the vector field \( d \) in the plaquette \( p \).

A discrete Stokes theorem, for a disk \( \mathcal{D} \) composed of plaquettes, reads

\[
\sum_{(ab) \in \partial \mathcal{D}} \phi_{ab} = 2\pi \sum_{p \in \mathcal{D}} Q_p.
\]

(11.14)

It can be proven by just rearranging the sums on the right-hand-side. The discrete Stokes theorem has two important consequences.

Jump in weak topological invariant happens when \( k_y = K_y \).

Total topological charge has to be 0. This is because the quantities we defined in the Brillouin zone are all periodic.

**Continuum Limit**

We can put this in a more convenient form by introducing a vector field \( \mathbf{A}(k_x, k_y) \), which is in some sense a gradient of \( \phi(k_x, k_y) \). This is easiest to define using square plaquettes (can be done for plaquettes of arbitrary shape), with corners

\[
k_a = (k_x - \delta k/2, k_y - \delta k/2); \quad k_b = (k_x + \delta k/2, k_y - \delta k/2);
\]

\[
k_c = (k_x + \delta k/2, k_y + \delta k/2); \quad k_d = (k_x - \delta k/2, k_y + \delta k/2).
\]

The definition reads,

\[
\mathbf{A}(k_x, k_y) = \frac{\phi_{ab} + \phi_{dc}}{2\delta k} \tilde{x} + \frac{\phi_{ad} + \phi_{bc}}{2\delta k} \tilde{y}.
\]

(11.15)
Figure 11.6: Brillouin zone, with $d$ vectors. $v = w_x = w_y = 1$.

It is easy to show that $Q_p$ corresponds to the flux of the curl of the vector field $A$ on the plaquette $p$.

The Stokes theorem above reads, for a disk $\mathcal{S}$ with boundary $\partial \mathcal{S}$,

$$\oint_{\partial \mathcal{S}} A \, ds = \int_{\mathcal{S}} \nabla \times A \, d^2S$$

(11.16)

Since $A$ is a gradient, its curl vanishes, except at points where it is not well defined.

**Linearizing Around the Nodes: Charge is Determinant**

Two-band case, linearized around a Weyl node $K$, we have, using the small distance $p = k - K$,

$$\hat{H}_{\text{C2D}} \approx \begin{pmatrix} p_x & p_y \\ v_{xx} & v_{xy} \end{pmatrix} \begin{pmatrix} \delta_x \\ \delta_y \end{pmatrix} + \frac{1}{\hbar} \begin{pmatrix} v_{ax} \\ v_{ay} \end{pmatrix} \begin{pmatrix} \sigma_x \\ \sigma_y \end{pmatrix};$$

(11.17)

$$v_{ax} = -w_a \sin K_a; \quad v_{ay} = w_a \cos K_a \quad \text{for } a \in \{x, y\}.$$  

(11.18)

For the Hamiltonian to be Hermitian, the matrix $v$ of coefficients must be real.

We can map how the vector field $d(p)$ winds around the node by solving the linearized equations for $d_x = 0$ and $d_y = 0$:

$$d_x = 0: \quad p_y = -\frac{v_{xx}}{v_{yx}} p_x; \quad d_y = 0: \quad p_y = -\frac{v_{yy}}{v_{yx}} p_x.$$  

(11.19)
11.4. **Edge States in Part of the Brillouin Zone**

The winding number is then found to be

\[ \nu = \text{sign} \det \nu. \quad (11.20) \]

11.3.2 **General, multiband case**

The formulas obtained through linearization also apply to the multiband case. In the vicinity of each node, only two energy levels are interesting anyway, we can use the restriction of the Hamiltonian to those levels.

To build more general formulas, use chiral symmetry of the Hamiltonian,

\[ H(k_x, k_y) = \begin{pmatrix} 0 & h(k_x, k_y) \\ h^\dagger(k_x, k_y) & 0 \end{pmatrix}. \quad (11.21) \]

We can apply the same formalism as before, but use the phase of the complex number \( \det h(k) \) instead of the phase of the vector \( d \).

- **vertex** \( k_a \) : \( \det [h(k_a)] \); (11.22a)
- **edge** \( k_a \rightarrow k_b \) : \( \phi_{ab} = \arg \left( \frac{\det h(k_b)}{\det h(k_a)} \right) \); (11.22b)
- **plaquette** \( p \) : \( Q_p = \frac{1}{2\pi} (\phi_{ab} + \phi_{bc} + \phi_{cd} + \phi_{da}) \), (11.22c)

11.4 **Edge States in Part of the Brillouin Zone**

Along a translation invariant edge, we can always see the model as coupled chiral symmetric chains. Zero-energy edge states appear when there is a local imbalance of sublattices. This imbalance remains after the coupling of the chains. Thus we expect that there are zero-energy bound states at the edge.

At the edge, the natural boundary condition might be not the one with all unit cells maintained. This complicates things in a real physical system.

11.5 **Coupling QWZ Layers for Weak Topological Insulator**

Same logic, applied to Qi-Wu-Zhang model.

\[ \hat{H}_{\text{Weyl}}(k) = \sin k_x \hat{\sigma}_x + \sin k_y \hat{\sigma}_y + (u + w \cos k_z + \cos k_x + \cos k_y) \hat{\sigma}_z. \quad (11.23) \]

This is the model (with \( w = 1 \)) cited in Vishwanath. We do not have chiral symmetry here, neither time-reversal symmetry, but we do have inversion symmetry and mirror symmetry along \( z \):

- **Inversion symmetry** : \( \hat{\sigma}_z \hat{H}_{\text{Weyl}}(k) \hat{\sigma}_z = \hat{H}_{\text{Weyl}}(-k) \); (11.24)
- **Mirror symmetry** : \( \hat{H}_{\text{Weyl}}(k_x, k_y, k_z) = \hat{H}_{\text{Weyl}}(k_x, k_y, -k_z) \). (11.25)
Neither inversion symmetry nor mirror symmetry play any important role here, they can be broken. For example, we can break inversion symmetry with \( w' \sin(k_z) \hat{\sigma}_x + w' \cos(k_z) \hat{\sigma}_y \).

Weak Chern Insulator.

Bulk invariant.

Edge states.

11.6 Transition from Trivial to Weak Topological Broadened: Topological Semimetals

Uncoupled layers: \( w = 0 \). As \( u \) is tuned, we transition from trivial \( (u < -2) \) to weak Chern insulator with \( Q = +1 \) \((-2 < u < 0)\), to weak Chern insulator with \( Q = -1 \) \((0 < u < 2)\), to topological \((u > 2)\). At the transition points, the gap closes along lines spanning the whole Brillouin zone.

The reason the transition broadens as a result of the coupling can be understood along the same lines as the lower dimensional case. We can treat the momentm \( k_z \) as a parameter. The three-dimensional model is then described by a torus that is moved periodically in \( d \)-space. INCLUDE A PICTURE.

In the presence of coupling, each gap closing along the lines at a single \( u \) value is turned into the trajectory of the node, at a finite range of \( u \).

\[
\begin{align*}
    & u < -2 - w : \quad \text{Trivial;} \\
    & -2 - w < u < -2 + w : \quad \text{Semimetal, } (0, 0, 0 \to \pm \pi); \\
    & -2 + w < u < -w : \quad \text{Weak Chern;} \\
    & -w < u < w : \quad \text{Semimetal, } (0, \pi, 0 \to \pm \pi) \text{ and } (\pi, 0, 0 \to \pm \pi); \\
    & w < u < 2 - w : \quad \text{Weak Chern;} \\
    & 2 - w < u < 2 + w : \quad \text{Semimetal, } (\pi, \pi, 0 \to \pm \pi); \\
    & 2 + w < u : \quad \text{Trivial.}
\end{align*}
\]

Weyl nodes are confined to four columns in the Brillouin zone, \( k_x = 0, \pi \) and \( k_y \) \( = 0, \pi \), every Weyl node at \( k \) comes with its inversion symmetric partner at \(-k\). Breaking inversion symmetry turns the columns into helical columns.

11.7 Topologically Protected Nodes: Gap Closing Points

11.7.1 Two-band Model: Nodes are Sources or Sinks of \( \tilde{d} \).

We can gain more insight into the nature of the nodes by taking a look at the \( \tilde{d} \) field. We can put the calculation into a convenient form using

\[
\hat{H}_{\text{Weyl}}(k) = d_0(k) \hat{\sigma}_0 + d(k) \hat{\sigma} = E_- (k) |u_- (k) \rangle \langle u_- (k)| + E_+(k) |u_+ (k) \rangle \langle u_+ (k)|,
\]

(11.26)
with $E_- (k) < 0$, $E_+ (k) > 0$, and $\langle u_+(k) | u_-(k) \rangle = 0$ for every momentum $k$. In our model, $d_0(k) = 0$, and hence, $E_-(k) = -E_+(k)$, which is important because it puts the nodes at the Fermi surface for half filling.

We will use a simplified notation:

$$\tilde{d}(k) = d(k)/|d(k)|; \quad (11.27)$$

$$k = k_a: \quad \tilde{d}_a = \tilde{d}(k_a); \quad |a\rangle = |u_-(k_a)\rangle. \quad (11.28)$$

The main idea of the calculation is best appreciated by starting in the continuum. In a volume $\mathcal{V}$ with surface $\mathcal{S} = \partial \mathcal{V}$, we can find the total number of sources/sinks of the vector field $d(k)$, by calculating the solid angle the vector field $\tilde{d}$ sweeps over as we scan over the surface.

For the discretization we will need a geometrical formula for the solid angle. We could do this using

$$\frac{1}{2} \Omega_{abc} = \tan^{-1} \left( \frac{(\tilde{d}_a \times \tilde{d}_b) \tilde{d}_c}{1 + \tilde{d}_a \tilde{d}_b + \tilde{d}_a \tilde{d}_c + \tilde{d}_b \tilde{d}_c} \right), \quad (11.29)$$

but this is a bit cumbersome, and it would restrict us to triangular plaquettes. We can do something more efficient, by using the knowledge obtained previously that the solid angle corresponds to the discrete Berry phase,

$$\frac{1}{2} \Omega_{abc} = F_{abc} = \arg \langle \langle a | b \rangle \langle c | a \rangle \rangle, \quad (11.30)$$

which is valid for plaquettes with any number of nodes on the boundary.
The discretization is obtained as

node $a$:

$|a\rangle$; \hspace{1cm} (11.31)

edge $a \rightarrow b$:

$\langle a | b \rangle$; \hspace{1cm} (11.32)

plaquette $p$:

$F_p = \arg \prod_{(ab) \in \partial p} \langle a | b \rangle$; \hspace{1cm} (11.33)

volume element $v$:

$Q_v = \frac{1}{2\pi} \sum_{p \in \partial v} F_p$. \hspace{1cm} (11.34)

We have to pay attention to the proper orientations of the boundaries: for plaquettes these are counterclockwise, for volume elements, the plaquettes should all be defined with normal oriented out from the middle of the volume element. We can plug in the arguments from the section on the Chern number, and obtain that the quantities $Q_p$ are integers, and they detect the nodes.

A discrete Gauss theorem, for a volume $\mathcal{V}$ composed of volume elements,

$$\sum_{(p) \in \partial \mathcal{V}} F_{ab} = \sum_{v \in \mathcal{V}} Q_v.$$ \hspace{1cm} (11.35)

This has two important consequences.

Jump in weak topoogical invariant happens when $k_y = K_y$.

Total topological charge has to be 0. This is because the quantities we defined in the Brillouin zone are all periodic.

**Continuum Limit**

We can put this in a more convenient form by introducing a vector field $\mathbf{B}(k_x, k_y)$, the Berry curvature. This is easiest to define using cubic volume elements (possible for volume elements of arbitrary shape), with corners

\[
\begin{align*}
k_a &= \left( k_x - \frac{\delta_k}{2}, k_y - \frac{\delta_k}{2}, k_z - \frac{\delta_k}{2} \right); \\
k_b &= \left( k_x + \frac{\delta_k}{2}, k_y - \frac{\delta_k}{2}, k_z - \frac{\delta_k}{2} \right); \\
k_c &= \left( k_x + \frac{\delta_k}{2}, k_y + \frac{\delta_k}{2}, k_z - \frac{\delta_k}{2} \right); \\
k_d &= \left( k_x - \frac{\delta_k}{2}, k_y + \frac{\delta_k}{2}, k_z - \frac{\delta_k}{2} \right); \\
k_e &= \left( k_x - \frac{\delta_k}{2}, k_y - \frac{\delta_k}{2}, k_z + \frac{\delta_k}{2} \right); \\
k_f &= \left( k_x + \frac{\delta_k}{2}, k_y - \frac{\delta_k}{2}, k_z + \frac{\delta_k}{2} \right); \\
k_g &= \left( k_x + \frac{\delta_k}{2}, k_y + \frac{\delta_k}{2}, k_z + \frac{\delta_k}{2} \right); \\
k_h &= \left( k_x - \frac{\delta_k}{2}, k_y + \frac{\delta_k}{2}, k_z + \frac{\delta_k}{2} \right).
\end{align*}
\]

The components of the field $\mathbf{B}$ are defined using the Chern numbers of the appropriate plaquettes, calculated so the normals are always along the positive direction, i.e.,

$$\mathbf{B}(k_x, k_y, k_z) = \frac{F_{adhe} + F_{bgcf}}{2\delta_k^2} \hat{x} + \frac{F_{aejfh} + F_{dhgc}}{2\delta_k^2} \hat{y} + \frac{F_{abcd} + F_{efgh}}{2\delta_k^2} \hat{z}. \hspace{1cm} \text{(11.36)}$$

It is easy to show that $Q_v$ corresponds to the integral of the divergence of the vector field $\mathbf{B}$ on the volume element $v$. 
The Gauss theorem above reads, for a volume element $\mathcal{V}$ with boundary $\partial \mathcal{V}$,
\[
\int_{\partial \mathcal{V}} B(k) d^2k = \int_{\mathcal{V}} \text{div} B(k) d^3k \tag{11.36}
\]

Because of the connection between the Chern number and the solid angles,
\[
B = \text{curl} \, \hat{d}. \tag{11.37}
\]

Since $B$ is a curl, its divergence vanishes, except at points where it is not well defined.

**Linearizing Around the Nodes: Charge is Determinant**

Two-band case, linearized around a Weyl node $K$, we have, using the small distance $p = k - K$,
\[
\hat{H} \approx (p_x \ p_y \ p_z) \begin{pmatrix}
  v_{xx} & v_{xy} & v_{xz} \\
  v_{yx} & v_{yy} & v_{yz} \\
  v_{zx} & v_{zy} & v_{zz}
\end{pmatrix} \begin{pmatrix}
  \hat{\sigma}_x \\
  \hat{\sigma}_y \\
  \hat{\sigma}_z
\end{pmatrix}; \tag{11.38}
\]

In general, the matrix $\nu$ of coefficients is real.

We can map how the vector field $d(p)$ winds around the node, ... The charge of the node is then found to be
\[
\nu = \text{sign} \det \nu. \tag{11.39}
\]

**11.7.2 General, multiband case**

The formulas obtained through linearization also apply to the multiband case. In the vicinity of each node, only two energy levels are interesting anyway, we can use the restriction of the Hamiltonian to those levels.

For more general formulas, we can plug in the formulas for Chern number of multi-band systems.
\[
\hat{H}(k_a) = \sum_{m=1}^{N_F} E_m(k_a) \langle a_m | a_m \rangle + \sum_{m=N_F+1}^{N_m} E_m(k_a) \langle a_m | a_m \rangle; \tag{11.40}
\]

We are interested in the nodes between the $N_F$th and the $(N_F + 1)$th energy states. This is crucial if for all $k$, we have $m \leq N_F \Rightarrow E_m(k) \leq 0$ and $m > N_F \Rightarrow E_m(k) \geq 0$.

The derivations for the two-band case remain valid, with the replacement $\langle a | b \rangle \rightarrow \det M^{(ab)}$. Put a discrete three-dimensional lattice on the Brillouin zone. We assign objects to the vertices, edges, plaquettes, and cubes of the lattice,

- **vertex** $a$: $\{ |a_1 \rangle, |a_2 \rangle, \ldots, |a_{N_F} \rangle \}$;
- **edge** $a \rightarrow b$: $\det M^{(ab)}$, with $M^{(ab)}_{mn} = \langle a_m | b_n \rangle$;
- **plaquette** $p$: $F_p = \text{arg} \prod_{(ab) \in \partial p} \det M^{(ab)}$;
- **volume element** $\nu$: $Q_v = \frac{1}{2\pi} \sum_{p \in \partial v} F_p$. 

Figure 11.8: Edge states of a Weyl semimetal. Color: inverse of the localization length of edge state. Fermi arcs are equipotential lines, shown in thick lines, continuous for energy $E = 0$ and above, slashed for negative energy. Spacing between equienergy lines is 0.2.

11.8 Fermi Arcs on Surface

The edge states exist only in parts of the Brillouin zone: those parts where the weak Chern number is nonzero. These are the Fermi arcs.

Problems

Nodes protected by extra symmetries

POSSIBLE EXERCISE: Even if chiral symmetry is broken, these other symmetries can stabilize the Weyl nodes. This is trivial in two-level systems, how does it work out in general?

Transition from weak topological

Discuss what happens to the two-dimensional chiral symmetric lattice model, as $w_x$ is tuned from $w_x = 0$ to $w_x = 10$, if $v = 1$ and $w_y = 2$.

Answer: If we repeat the same process, but with topological chains, $v < w_y$, we have

$$\begin{align*}
\text{If } & w_x < w_y - v : & \text{Weak topological; } & (11.41) \\
\text{If } & w_y - v < w_x < v + w_y : & \text{Semimetal; } & (11.42) \\
\text{If } & v + w_y < w_x : & \text{Weak topological. } & (11.43)
\end{align*}$$

Paths of nodes when $v$ is tuned

If $v$ is tuned, show that, assuming $w_y < w_x$ without loss of generality,

$$w_x - w_y \leq v \leq w_x + w_y; \quad X_y \to M$$

(11.44)
Figure 11.9: Edge states of a Weyl semimetal. Color: inverse of the localization length of edge state. Fermi arcs are equipotential lines, shown in thick lines, continuous for energy $E = 0$ and above, slashed for negative energy. Spacing between equienergy lines is 0.2.
